

Activity: ransomware ANALYSIS

Ransomware is a type of malicious software that locks users out of their system or data using different methods to force them to pay a ransom. Most often, such programs encrypt files on an infected machine and demand a fee to be paid in exchange for the decryption key. Additionally, such programs can be used to steal sensitive information from the compromised computer and even conduct DDoS attacks against affected organizations to pressure them into paying

Activity

Your organization's network has been compromised by WannaCry ransomware. Fortunately, daily backups are made and all computers and servers have been restored. In addition, the corresponding security patches have been applied that mitigate the spread of this malware through the internal network.

This malware has the peculiarity that it has a kill switch, consisting of a domain to which the malware connects before doing anything and, if this domain exists, for its execution.

Your objective is to find said domain (without http://) in order to save the world.

NOTE: it is important that you run the binary in a virtual environment.

The binary is inside the zip file. The zip password is *infected*

NOTE: Be sure to:

Work on isolated machines (or isolated virtual machines)

Do **not** install guest additions

Do **not** put the shared network adapter, only on the internal network. (no NAT, no bridge adapter)

Remember: All caution is insufficient when dealing with malware
